# Overweight and obesity as risk factors in hypertension Study of the working population 

Irena Maniecka-Bryla, Monika Szymocha, M. Bryla<br>Chair of Social \& Preventive Medicine, Medical University of Lodz

## Key words

Obesity; arterial hypertension; working population; diseases

#### Abstract

Summary Background: Obesity is one of the major epidemiological problems in developed countries; it is also one of the main risk factors for hypertension. It is estimated that about $80 \%$ of hypertension cases in Poland are related to an increase in body mass. Objective: The main aim of the study was to investigate overweight and obesity in terms of being risk factors for arterial hypertension. Methods: The study population consisted of randomly selected working adults living in the Swietokrzyskie province in Poland. The research tools included a questionnaire inquiring about data concerning healthy habits, as well as measuring blood pressure, body mass, beight and waist circumference. Results: The study group consisted of 599 people ( $55.3 \%$ females and $44.7 \%$ males) aged 18-67; 67.8\% of the study subjects were white-collar workers and $36.2 \%$ were blue-collar workers; $44.9 \%$ of our respondents were overweight and $22.8 \%$ were obese. Hypertension occurred significantly more frequently (p<0.01) among blue-collar (54.4\%) than among white-collar workers (43.2\%). Our analysis showed a statistically significant difference in the prevalence of hypertension among employees of various economic sectors ( $p<0.01$ ). Hypertension and body mass increase were more frequent among men ( $p<0.001$ ). Hypertension occurred in people with higher levels of Body Mass Index (BMI) and Waist Circumference (WC) ( $p<0.001$ ). Conclusion: The data confirm the correlation between frequency of overweight and obesity and prevalence of arterial hypertension Active and proper prevention of obesity among the working population could lower the risk of arterial hypertension.

## Riassunto

«Sovrappeso e obesità come fattori di rischio per l'ipertensione - Studio di una popolazione lavorativa». Introduzione: L’obesità è uno dei principali problemi epidemiologici nei paesi sviluppati, ed è anche uno dei principali fattori di rischio di ipertensione. Si stima che circa l' $80 \%$ dei casi di ipertensione in Polonia è in relazione con un aumento della massa corporea. Obiettivi: L'obiettivo principale dello studio è stato indagare sovrappeso e obesità come fattori di rischio per l'ipertensione arteriosa. Metodi: La popolazione allo studio era costituita da un campione casuale di lavoratori adulti che vivono nella provincia di Swietokrzyskie in Polonia. Gli strumenti di ricerca hanno incluso l'uso di un questionario per indagare le abitudini di vita, la misurazione della pressione arteriosa, della massa corporea, dell'altezza e della circonferenza al punto vita. Risultati: Il gruppo studiato era formato da 599 persone (55,3\% femmine e 44,7\% maschi) di età compresa tra 18-67. Il 67,8\% dei soggetti erano impiegati e il

[^0]$36,2 \%$ operai. Tra gli impiegati le donne avevano una frequenza significativamente maggiore ( $p<0,001$ ) rispetto agli uomini ( $81,0 \%$ e 42,5\% rispettivamente). In generale l'ipertensione era presente con frequenza significativamente maggiore ( $p<0,01$ ) tra gli operai $(54,4 \%)$ che tra gli impiegati (43,2\%). Lo studio ba rivelato che il $44,9 \%$ degli intervistati era in sovrappeso e il $22,8 \%$ era obeso, senza differenze di prevalenza nei diversi settori. Ipertensione e aumento della massa corporea sono risultati più frequenti tra i maschi ( $p<0,001$ ). L'ipertensione riguardava le persone con livelli più elevati di indice di massa corporea (BMI) e circonferenza della vita $(W C)(p<0,001)$. Conclusione: Lo studio conferma la relazione tra la frequenza di sovrappeso e obesità e la prevalenza di ipertensione arteriosa. La prevenzione attiva e corretta dell' 'obesità tra la popolazione lavorativa può attenuare il rischio di ipertensione arteriosa.

## Introduction

The working population of every European country benefits from occupational health services as a subsystem of health care differentiated by the range, form and structure, depending on the respective national legislative framework. The scope of these services is determined by multiple factors, including the level of financial resources allocated to this section of medicine, which in turn stems from the organization $(6,18)$ and financing arrangements of the healthcare system (37). According to WHO data published in 2009, for instance, whereas in Italy total expenditure on health as a proportion of GDP rose from $7.3 \%$ in 1996 to $8.8 \%$ in 2005, in Poland it remained relatively stable in the same period at approximately $6.0 \%$. The structure of occupational health services is largely influenced by recent transition due to emerging challenges and the evolution of the role of occupational health physicians $(9,11,12)$. Nowadays it is emphasized that the key to maintain the effective functioning of the workforce is the concept of well-being, which encompasses more than just one's state of health; it is also a reflection of one's satisfaction with work and life', '...For the health components of wellbeing, there is a growing body of evidence on the effectiveness of workplace intervention for occupational outcomes (e.g. musculoskeletal disorders, mental health) and personal factors (e.g. smoking, being overweight)' (31). The activities performed by occupational health physicians should include a wide range of tasks in the field of health promotion and health education, which has often been emphasized in Italian literature on the subject ( $3,7,21,22,30$ ).

Occupational health physicians tend to encounter an increasing number of obese patients. The scale of obesity is enormous. 'The World Health Organization Regional Office for Europe recently stated that 300 million people in the world are obese. The prevalence of obesity has increased by $25.0 \%$ in the last 20 years. In Europe 14 million people are overweight, 6 million obese...' (32). There is no doubt that obesity constitutes a risk for several vascular, metabolic and neoplastic diseases (24). The prevalence of overweight and obesity is also widespread among healthcare workers (2). Because of the high prevalence, this phenomenon deserves more in-depth research studies based on state-of-the-art methodology. Obesity is defined as an increase in body weight due to an excessive accumulation of fatty tissue exceeding correct values established for age, gender and race. In 1997 the WHO recognised obesity as a chronic state, requiring treatment, that facilitates the development of other diseases and is associated with higher mortality (14, 36). Obesity therefore became a serious medical problem and is getting more and more widespread, turning into an epidemic in developed countries (28). Nowadays the most frequently used indicator of the degree of obesity is the Quetelet's indicator BMI (BMI Body Mass Index). According to the World Health Organization's classification, overweight is diagnosed when the BMI remains in the range of 25$29.9 \mathrm{~kg} / \mathrm{m}^{2}$, and obesity begins when the level of $30 \mathrm{~kg} / \mathrm{m}^{2}$ is exceeded. However, this indicator does not provide diagnostically significant information about the distribution of fatty tissue. In order to assess the visceral kind of obesity, we use a simple anthropometric parameter: waist circumference
$(17,23)$. The impact of the obesity epidemic on health is related not only to the disease itself, but also to the consequences of many illnesses, which comprise obesity as a confirmed risk factor. One of the most significant diseases is hypertension. The epidemiology of obesity, like the epidemiology of hypertension, indicates the existence of a strong cause-and-effect relationship between both diseases. Research has shown that a high value of hypertension is more frequent in overweight or obese persons. It is estimated that $80 \%$ of hypertension in Poland occurs in people with BMI $>25 \mathrm{~kg} / \mathrm{m}^{2}$ (4, $8,10,15,25)$. According to the 2003 recommendations of the European Society of Hypertension/European Society of Cardiology (ESH/ ESC), confirmed in 2007 by Polish and European experts, blood pressure below 120 mm Hg is considered to be optimal for systolic blood pressure (SBP) and below 80 mm Hg for diastolic blood pressure (DBP). The correct pressure should be, respectively, 120-129 mm Hg for SBP and/or 80-84 mm Hg for DBP, while high normal blood pressure should be $130-139 \mathrm{~mm} \mathrm{Hg}$ for the SBP and/or $85-89 \mathrm{~mm} \mathrm{Hg}$ for the $\operatorname{DBP}(1,19,38)$.

## AIM

The aim of this study was to assess the correlation between the incidence of overweight and obesity and hypertension in a working population in
the Swietokrzyskie province. The aim of a detailed analysis was the evaluation of the prevalence of abdominal obesity and its relationship with the occurrence of hypertension in the study sample.

## Materials and methods

The study conducted in the period from June to December 2009 comprised a sample of 599 persons (331 women, 268 men), occupationally active, aged 18 to 67 years, selected at random from the population employed in the Swietokrzyskie province. The research tool was a self-designed interview questionnaire consisting of 34 questions related to the subjects' lifestyle, which were divided into thematic blocks. A condition of enrolment was the consent of the person selected for the study. All study participants had their body mass (kg) and body height ( cm ) measured, together with waist circumference ( cm ), and measurement of blood pressure was performed twice, according to current expert recommendations. BMI and the presence of abdominal obesity were assessed on the basis of the collected data and waist circumference. The classification of obesity according to the aforementioned parameters is presented in table 1. Hypertension was diagnosed when systolic blood pressure was $\geq 140 \mathrm{~mm} \mathrm{Hg}$ and/or diastolic blood pressure was $\geq 90 \mathrm{~mm} \mathrm{Hg}$. The classification of blood pressure according to degrees of hypertension is presented

Table 1 - The classification of obesity according to body mass index and waist circumference, together with the risk of metabolic complications

| Degree of obesity | $\mathrm{BMI}\left(\mathrm{kg} / \mathrm{m}^{2}\right)$ | Risk of complications |  |
| :--- | :---: | :--- | :--- |
| Normal | $18.5-24.9$ |  | Small |
| Overweight | $25.0-29.9$ | Insignificantly increased |  |
| Obesity I | $30.0-34.9$ | Increased |  |
| Obesity II | $35.0-39.9$ | Severe |  |
| Obesity III | $>40$ | Very severe |  |
| Degree of obesity | Waist $(\mathrm{cm})$ women | Waist $(\mathrm{cm})$ men | Risk of complications |
| Normal | $<80$ | $<94$ | Small |
| Overweight | $80-88$ | $94-102$ | Increased |
| Obesity | $>88$ | $>102$ | Severe |

in table 2. The results obtained, after encoding, were inserted into an Excel spreadsheet. Statistical analysis comprised descriptive methods and the methods of statistical inference.

The following characteristics were calculated for the measurable features: the arithmetic mean ( $\bar{x}$ ), standard deviation (s), the median ( Me ) and the coefficient of variation ( $\mathrm{v} \%$ ), providing also the minimum and maximum values. The chi ${ }^{2}$ test of independence was used in order to compare the incidence of individual variations of the characteristics within the study groups and in order to examine the relationship between the characteristics used. All calculations were made at a level of significance of $p<0.05$. The rectilinear correlation coefficient r was used to study the relationship between the measurable characteristics and the t-Student test made it possible to assess its significance. The indicators calculated for small samples were presented in the form of fractions, and in the case of large samples they were expressed as percentage.

## Results

The characteristics of the sample taking into account the location and dispersion measures for individual features are presented in table 3.
$67.8 \%$ of the study subjects were white-collar workers and $36.2 \%$ were blue-collar workers. Women performed white-collar jobs significantly more frequently ( $\mathrm{p}<0.001$ ) than men ( $81.0 \%$ and $42.5 \%$ respectively). The majority of our study subjects had a job with fixed hours (74\%). Women
were employed at fixed hours more often than men ( $77.6 \%$ compared to $69.6 \%$ ) ( $\mathrm{chi}^{2}=5.221, \mathrm{p}<0.05$ ).

Men and women also differed significantly according to the employment sector in which they worked ( $\mathrm{chi}^{2}=89.337, \mathrm{p}<0.001$ ). Most women worked in manufacturing - $26 \%$, administration $17.5 \%$ and education $-15.1 \%$, whereas over half of the male subjects ( $52 \%$ ) worked in manufacturing.

The results indicate that only $37.7 \%$ of the subjects in the study group had correct and optimal systolic blood pressure. In addition, $19.9 \%$ of respondents were characterised by a high correct blood pressure. Mild hypertension occurred in $28.4 \%$ of respondents, and all other persons were characterised by moderate ( $11.5 \%$ ) and severe (2.5\%) hypertension. The average systolic blood pressure for the entire study population was 135 mm Hg .

Analysis of the relationship between systolic pressure and gender revealed statistically significant relationships of moderate strength between these traits (chi ${ }^{2}=69.944, \mathrm{p}<0.001, \mathrm{C}=0.32$ ). It was found that significantly more men than women were characterised by both mild and also moderate and severe hypertension. However women more frequently had an optimal and correct blood pressure. High normal blood pressure in both gender groups occurred with similar frequency (table 4).

More than half of the respondents had an optimal or correct diastolic blood pressure (53.0\%), and a correct high blood pressure occurred in $12.5 \%$ of patients; $34.5 \%$ of respondents suffered from hypertension, with $10.5 \%$ having moderate hypertension and $3.5 \%$ severe hypertension. The average di-

x - arithmetic mean, Me - median, Mo - modal; s - standard deviation; v - coefficient of variation, min - minimum value, max - maximum value for the individual characteristics in the whole group
astolic blood pressure for the entire population was 84.3 mm Hg. A statistically significant weak correlation between diastolic blood pressure and gender was revealed ( $\mathrm{chi}^{2}=42.380, \mathrm{p}<0.001, \mathrm{C}=0.26$ ). As in the case of systolic blood pressure incidence analysis, significantly more men than women were characterized by hypertension (mild, moderate and severe). The detailed distribution of the data here discussed is shown in table 5.

Analysis of the relationship between systolic blood pressure and job type indicated that optimal,
correct and high correct pressure was significantly more common among white-collar workers than blue-collar workers ( $\mathrm{chi}^{2}=27.720, \mathrm{p}<0.01$ ), Among the blue-collar workers, moderate and severe hypertension was significantly more frequent (table 6).

We obtained a statistically significant relationship between job type (white collar/blue collar) and systolic hypertension ( $\mathrm{chi}^{2}=13.915$; $\mathrm{p}<0.001$ ) in our sample. Systolic hypertension was significantly more prevalent among blue-collar workers (52.5\%) than white-collar workers (36.8\%) (table 7).

chi $^{2}=3.201 ; p>0.05$

Optimal and correct diastolic blood pressure occurred significantly more often among white-collar than blue-collar workers (chi ${ }^{2}=14.918, \mathrm{p}<0.01$ ). Severe and moderate diastolic hypertension was observed significantly more frequently among bluecollar workers. Mild hypertension was almost equally prevalent in both categories, whereas high correct RRD was more widespread among bluecollar workers, just like hypertension - table 8.

No statistically significant difference occurred between the job type (white-collar/blue-collar) and diastolic hypertension ( $\mathrm{p}>0.05$ ). Diastolic hypertension was observed among white-collar and bluecollar workers with similar frequency ( $32 \%$ and 39\%) - table 9.

Statistical analysis indicated a statistically significant difference in the prevalence of general hypertension, systolic hypertension and diastolic hypertension as well as both types of hypertension among males and females in the white-collar category ( $p<0.25 ; \mathrm{p}<0.01 ; \mathrm{p}<0.001$ ). It was observed that each type of hypertension was significantly more common among male study subjects. Howev-
er, there was no statistically significant difference in this field between males and females in the bluecollar job category concerning any type of hypertension ( $p>0.05$ ). Regardless of the job category, males tended to suffer significantly more often from systolic hypertension ( $\mathrm{p}<0.01$ ), both hypertension types combined ( $\mathrm{p}<0.001$ ) and general hypertension ( $\mathrm{p}<0.001$ ) - tables 10, 11.

A comparison of blue-collar and white-collar workers (males and females included) indicated that diastolic hypertension was significantly more prevalent among blue-collar workers (15.7\%) than among white-collar workers (11.5\%) - p>0.05. Nevertheless, both types of hypertension taken together (RRS + RRD) occurred more often among white-collar workers ( $\mathrm{p}<0,01$ ), The respective percentage amounted to $2.3 \%$ and $6.2 \%$. We did not find any statistically significant differences in hypertension prevalence between blue-collar and white-collar females ( $\mathrm{p}>0.05$ ), whereas diastolic hypertension prevalence was higher in white-collar (12.5\%) than in blue-collar workers ( $\mathrm{p}<0.01$ ). Generally, hypertension (RRS + RRD) occurred signif-

icantly more frequently ( $\mathrm{p}<0.01$ ) among blue-collar workers (54.4\%) than among white-collar workers (43.2\%) - table 12.

Our statistical analysis confirmed a statistically significant difference in hypertension prevalence among representatives of various employment sectors ( $\mathrm{p}<0.01$ ). Hypertension was most common in the construction industry (the fraction was 0,48 , so it concerned almost half of the study subjects) followed by manufacturing (fraction: 0,36 ) and trade $(0,34)$. Hypertension occurred significantly more often among construction workers than in the following sectors: administration, property markets and financial services, education, healthcare and
service industry ( $\mathrm{p}<0.05 ; \mathrm{p}<0.01$ ). There was no significant difference in hypertension prevalence in the following sectors: administration, assets and securities, construction, education, trade, manufacturing, health services, transport, service industry ( $\mathrm{p}>0.05$ ), while it was significantly higher among workers in the manufacturing sector compared to the aforementioned sectors ( $\mathrm{p}<0.05 ; \mathrm{p}<0.01$ ) - table 13.

A comparison of all employment sectors combined did not give a statistically significant difference in the prevalence of overweight and obesity in the following sectors: administration and health care, education and manufacturing, construction and manufacturing ( $\mathrm{p}<0.05$ ) - table 14

| Total | 331 | 100.0 | 268 | 100.0 | 599 | 100.0 |

The research has shown that $67.7 \%$ of the study group members were characterised by excessive body weight; the sample was dominated by people who were overweight (44.9\%), whereas those with obesity accounted for $22.8 \%$ of total respondents. It was also found that women had a normal body weight significantly more frequently than men, while the latter are more prone to develop conditions of overweight or obesity - especially to I and II degree. A statistically significant, weak correlation between BMI and the gender of respondents
was observed $\left(\right.$ chi $\left.^{2}=38.013, \mathrm{p}<0.001, \mathrm{C}=0.24\right)$. The structure of the respondents in terms of gender and BMI values is shown in table 15.

Analysis of the relationship between BMI and age of the respondents indicated a statistically significant correlation between the measured traits ( $\mathrm{chi}^{2}=33.330, \mathrm{p}<0.001$ ). The incidence of overweight and obesity, expressed by means of fractions, increased with the respondents' age, reaching in the case of the oldest respondents respectively 0.46 (overweight) and 0.32 (I degree obesity ). It is

chi' ${ }^{2}=23.053 ; \mathrm{p}>0.05$
worth noting that the incidence of II and III degree obesity is similar in all age groups (figure 1).

A statistically significant correlation between BMI and systolic blood pressure levels was found
(chi² $=99.634, \mathrm{p}<0.001, \mathrm{C}=0.38$ ), as well as between BMI and diastolic blood pressure ( $\mathrm{chi}^{2}=66.204$, $\mathrm{p}<0.001, \mathrm{C}=0.32$ ). In both cases, the subjects with BMI indicating overweight or obesity were more

Figura 1 - Relationship between BMI level and age in the study group
prone to developing hypertension than the patients with standard body weight (figures 2,3 ). It was observed that both systolic and diastolic blood pressure correlated with age ( $\mathrm{p}<0.001$ ).

Analysis of the study group, which was based on waist circumference, showed that $35.3 \%$ of the subjects were overweight and a further $28.7 \%$ had abdominal obesity. The structure of the men and
women under study, in terms of their waist circumferences, is shown in figure 4. A correlation was also found between waist circumference and systolic blood pressure of women $\left(\mathrm{R}^{2}=0.1475\right)-$ figure 5 , and waist circumference and diastolic blood pressure of women $\left(\mathrm{R}^{2}=0.1083\right)$ - figure 6 . No correlation of this kind was observed in male subjects.

## Discussion

According to the data from the NHANES study (National Health and Nutrition Examination Survey) it was shown that excessive weight affected $65.7 \%$ of the U.S. population, $30.6 \%$ of which was found to be obese, and $5.1 \%$ gigantically obese. The incidence of obesity in Europe is estimated to be $10-20 \%$ in men and $10-25 \%$ in women. According to the NATPOL PLUS study, excessive body weight is a feature of $53 \%$ of the Polish population and the LIPIDOGRAM 2004 study revealed that $48 \%$ of men were overweight and $32.78 \%$ were obese, while in case of women, these values were respectively $39.16 \%$ and $31.22 \%$. According to the WOBASZ national survey, carried out from 2003 to 2005 in the Swietokrzyskie province, $26.5 \%$ of women and $38.6 \%$ of men were found to be overweight, and respectively $20.5 \%$ and $20.4 \%$ were found to be obese $(8,10,38)$.

The study showed that the percentage of overweight people in the working population of the Swietokrzyskie province was 44.9\% (39.6\% women and $51.5 \%$ men), while the percentage of obese people was $22.8 \%$ ( $18.1 \%$ women and $28.7 \%$ men); comparable results were obtained in the LIPIDOGRAM 2004 study. An increase in the prevalence of overweight subjects among both genders can be observed, together with a decrease in the number of obese women, compared to the WOBASZ study. Analysis of the research conducted in Poland indicates that the percentage of people with excessive body weight was lower in the previous years, compared to the currently observed situation, especially in the case of males. The percentage of overweight and obesity in men found by the POL-MONICA Warszawa study was about $67 \%$ in the early 1990's and increased to about $72 \%$ in 2001, whereas it decreased in the case of women, falling from about $64 \%$ to $60 \%$. A similar trend was observed with the CINDIWHO project, carried out in Lodz in the 18-64 years age group. In the period from 1991 to 2001, the incidence of overweight in men increased from $37.7 \%$ to $41 \%$ and obesity from $13.5 \%$ to $16.4 \%$; an opposite trend was observed in women: the percentage of overweight cases decreased from
$32.6 \%$ to $26.9 \%$ and for obesity the results ranged from $21.2 \%$ to $16.9 \%$ (13).

The results of numerous scientific studies conducted in other countries revealed an association between BMI and arterial hypertension values and also provided evidence of the influence of obesity on the development of arterial hypertension (33). In the HOPE study, where the average value of the BMI indicator was $28 \mathrm{~kg} / \mathrm{m}^{2}, 47 \%$ of subjects had arterial hypertension. A very significant correlation was observed between visceral obesity and presence of arterial hypertension. The results on the NHANES study demonstrated that hypertension was more frequently the problem of persons with both increased BMI and waist circumference, which indicate overweight, than of persons with the high BMI and normal waist circumference (27). According to the WOBASZ project, the incidence of hypertension in Poland was about $36 \%$. Men were more likely to suffer from hypertension (41\%) than women (32.9\%), nevertheless optimal blood pressure values were found only in $12 \%$ of men and $30 \%$ of women, while the NATPOL PLUS study revealed the presence of hypertension in $29 \%$ of the entire population. In the light of the aforementioned data the results of this study are not promising, since the average systolic blood pressure was found to be 135 mmHg , and the average diastolic pressure 84.3 mmHg . Analysis of the correlation between blood pressure and gender of the respondents revealed that $42.4 \%$ of the subjects had increased systolic pressure, but was more characteristic in men (56.4\%) than in women (31.1\%). In the case of increased diastolic blood pressure values, frequencies were respectively $34.6 \%$, $45.1 \%$ and $25.9 \%$. The results obtained in men were especially worrying. Similar data were forthcoming from the PENT study, where hypertension was diagnosed in $44.2 \%$ of the respondents aged 18 years and more ( $43 \%$ women and $45 \%$ men), as well as from the WISHE study, where hypertension was diagnosed in $56 \%$ of men and $60 \%$ of women, nevertheless the study was conducted in a study group over 65 years of age (16. 26). Hypertension in blue collars can be attributed, at least in part, to the different life-style and maybe also to the different sex distribution in the examined population.

The study also confirmed the existence of a correlation between systolic blood pressure and diastolic blood pressure values, and BMI values, although the relationship was stronger in the first case. An increased systolic pressure was observed in $45 \%$ of overweight patients and in $65 \%$ of obese subjects, while diastolic pressure was increased in $37 \%$ and $50 \%$ of the respondents respectively. Similar results were obtained in the Skrzypek-Wanha et al study, where it was observed that the largest percentage of patients with correct blood pressure values was found in the group having a $\mathrm{BMI}<25$, while in the group of obese subjects persons with correct blood pressure were in a minority (34). Also in the Framingham study it was demonstrated that $70 \%$ of men and $60 \%$ of women suffering from arterial hypertension were obese, and the NHANES III study confirmed the correlation between BMI values and levels of arterial pressure. According to the IDEA study, abdominal obesity affected $29 \%$ of men and $48 \%$ of women in the world $(29,35)$. The WOBASZ study indicated that in Poland $28.3 \%$ of men and $40.4 \%$ of women had developed abdominal obesity. In the aforementioned studies it was found out that the percentage of people who were overweight and suffering from abdominal obesity was lower, compared to Poland - in the case of women the results were respectively $33.6 \%$ and $31.5 \%$, while in the case of men they were $37.3 \%$ and $25.4 \%$. Similarly to the findings of the Nurses' Health Study research, the OT indicator correlated significantly with blood pressure values in women. However, no such correlation was observed in men (39).

The results of this study also confirmed the correlation between the levels of arterial blood pressure and the age of the respondents. A similar correlation between the aforementioned variables was revealed in the research conducted by Maciak et al and in the Nurses' Health Study $(19,20)$.

The results of the studies indicate that special attention should be paid to the need to undertake preventive action among working people. The aim of such actions would be to limit the incidence of overweight and obesity and, as a result, reduce the consequences, such as obesity-related arterial hypertension. It is advisable to facilitate the implementation of occupational health promotion in the workplace.

## Conclusions

The high prevalence of overweight and obesity, as well as hypertension, is an significant health problem in the population of people working in the Swietokrzyskie province;

Statistically significant relationships ( $\mathrm{p}<0.001$ ) were demonstrated between the incidence of overweight and obesity and hypertension in the study group.

There is an urgent need to take active measures aimed at the prevention of obesity among occupationally active people, which can reduce the risk of hypertension.

No potential conflict of interest relevant to THIS ARTICLE WAS REPORTED
